Abstract

The spectral sensitivities of image capture devices should be carefully designed to guarantee colorimetric color reproduction. As a standard color test chart, ISO/DIS 12641 is conveniently used for calibrating the scanners or printers. However, its color gamut is not wide enough to evaluate the devices such as digital camera & display systems because the chart is a photographic print and the color distributions are not uniform. In this paper, we propose a virtual color target to estimate the spectral goodness of color devices. A virtual spectrum with given $L^*a^*b^*$ value is generated from the fundamental metamer uniquely obtained by inverse projection of XYZ tristimulus value and an addition of arbitrary metameric black spectrum. The goodness of typical color input sensors is measured by this virtual spectral target and compared in consistent with actual color chips.

Introduction

Various color targets are used to estimate the performance of color devices. Standard test chart ISO/DIS 12641 however, have not wide gamut enough to evaluate such device as digital camera and the color distributions are not uniform because the chart is a photographic print. We proposed a virtual color target 4 with sinusoidal spectral power distributions (sine SPDs) and applied it to the estimation of color filter sets 5,6. But it was difficult to generate the sine SPDs with uniform distributions in CIELAB space. This paper presents a method to synthesize a set of color spectra with wide gamut distributed uniformly in CIELAB space. A virtual spectrum with given $L^*a^*b^*$ value is generated from the fundamental metamer with an addition of metameric black. The spectral goodness of color sensors is measured by the fundamental spectral error $E[||e||^2]$ after versus before passing through the sensors as introduced by Vora and Trussell 2. The reliable values of $E[||e||^2]$ could be obtained for typical color sensors and compared with the results by actual chips and sine SPDs.

2. Color Sensors' Error in Fundamental Spectra Detection

An input SPD $C(\lambda)$ is described as an n-dimensional vector

$$C=[C_1, C_2, \dots, C_n]^t; C_i=C(\lambda_i), t=\text{transpose} \quad (1)$$

By the projection of C onto Human Visual Subspace(HVS),

C is decomposed into the fundamental metamer C^* and residual B by Cohen 3

$$C=C^*+B, \quad C^*=P_v C, \quad B=(I-P_v)C \quad (2)$$

where I is the identity matrix and

$$P_v=A_L(A_L^t A_L)^{-1} A_L^t, \quad A_L=LA \quad (3)$$

P_v denotes the orthogonal projection operator onto HVS from input color vector space and a residue B is called metameric black with zero stimulus not perceived to human vision. Where A and A_L denote the CIE color matching matrix and that by biased with illuminant L .

P_v extracts a fundamental metamer C^* that carries the tristimulus vector T as

$$T=A_L^t C=A_L^t C^* \quad (4)$$

The projection operator P_F for a set of tri-color sensors is obtained by

$$P_F=F(F^t F)^{-1} F^t \quad (5)$$

where, C is the $n \times 3$ tri-color sensor sensitivity matrix with filter functions, red $r(\lambda)$, green $g(\lambda)$, and blue $b(\lambda)$. Thus, the fundamental metamer C_F^* through a color sensor for input C is given by the projection operator P_{FV} onto HVS

$$C_F^*=P_{FV} C, \quad P_{FV}=P_v P_F \quad (6)$$

Here, input spectrum C is decomposed into C_F^* and residual B_F through color sensor in HVS like as

$$C=C_F^*+B_F \quad (7)$$

Tristimulus vector T for C under illuminant L is given by

$$T=A_L^t C=A_L^t (C_F^*+B_F)=A_L^t (C_F^*+B_F)=T_F-\Delta T_F \quad (8)$$

$$T_F=A_L^t C_F^*, \quad \Delta T_F=T_F-T=-A_L^t B_F \quad (9)$$

Where, T_F and ΔT_F denote the tristimulus vector captured by color sensor and its error caused by the mismatch between sensor matrix F and color matching function A_L . Furthermore, T_F can be separated into two parts as follows.

$$T_F=A_L^t C_F^*=A_L^t P_{FV} C=A_L^t P_{FV} (C^*+B)=T_{FC}+\Delta T_B \quad (10)$$

$$T_{FC}=A_L^t P_{FV} C^*, \quad \Delta T_B=P_{FV} B \quad (11)$$

T_{FC} and ΔT_B mean the sensor responses to fundamental metamer C^* and to metameric black B . Here we should notice the sensor makes non-zero response ΔT_B to B , though human vision has zero stimulus $A_L^t B=0$. In short, the

tristimulus error $\Delta\mathbf{T}_F$ is composed of $\Delta\mathbf{T}_C$ and $\Delta\mathbf{T}_B$

$$\Delta\mathbf{T}_F = \Delta\mathbf{T}_C + \Delta\mathbf{T}_B, \quad \Delta\mathbf{T}_C = \mathbf{T}_{FC} - \mathbf{T} \quad (12)$$

Where, $\Delta\mathbf{T}_C$ corresponds to the fundamental error and $\Delta\mathbf{T}_B$ to the metameric black error. The error $\Delta\mathbf{T}_B$ caused by metameric black \mathbf{B} should be taken into account.

The spectral goodness of sensor is measured by the mean square error $E[\|\mathbf{e}\|^2]$ between true fundamentals \mathbf{C}_n^* and sensed fundamentals \mathbf{C}_{Fn}^* for $n=1\sim N$ test color chips by

$$E[\|\mathbf{e}\|^2] = \left[\frac{1}{N} \sum_{n=1}^N (\mathbf{C}_{Fn}^* - \mathbf{C}_n^*)^2 \right] \quad (13)$$

3. Generation of Virtual Spectral Color Target

The following three different color targets are used for color sensors' quality test.

- (1) ISO/DIS 12641 standard color target (real 264 chips)
- (2) Sine SPDs (virtual chips)
- (3) Synthesized SPDs (proposed virtual LAB chips)

Fig.1 (a) shows the color distributions for ISO/DIS 12641 and (b) for sine SPDs(1000 chips). The distributions of ISO/DIS 12641 are limited inside the gamut of photographic print and are not uniform. On the other hand, sine SPDs can cover wider gamut and may be effective test stimuli for digital cameras, but are not still distributed in uniform.

Here, we generated the virtual spectra with given CIELAB value $\mathbf{C}_{LABn} = [L_n^*, a_n^*, b_n^*]^t$ as the following steps.

[Step 1] Convert the CIELAB value \mathbf{C}_{LABn} into CIE-XYZ tristimulus value $\mathbf{T}_n = [X_n, Y_n, Z_n]^t$.

[Step 2] Compute the fundamental spectrum \mathbf{C}_n^* from \mathbf{T}_n .

[Step 3] Add a metameric black component \mathbf{B}_n to \mathbf{C}_n^* .

Thus, finally we get the color spectrum

$$\mathbf{C}_n = \mathbf{C}_n^* + \mathbf{B}_n \quad (14)$$

An input spectrum \mathbf{C}_n is estimated by using pseudo-inverse transform from Eq. (4) as

$$\mathbf{C}_n = \mathbf{P}_{INV} \mathbf{T}_n + (\mathbf{I} - \mathbf{P}_{INV} \mathbf{A}_L) \mathbf{V} \quad (15)$$

where, \mathbf{V} means an arbitrary vector. Here, we should notice the 1st term of Eq. (15) is equal to the fundamental metamer \mathbf{C}_n^* and the 2nd term denotes a metameric black.

Thus the fundamental spectrum \mathbf{C}_n^* is simply recovered from \mathbf{T}_n using colorimetric pseudo-inverse projection operator \mathbf{P}_{INV} given by

$$\mathbf{C}_n^* = \mathbf{P}_{INV} \mathbf{T}_n, \quad \mathbf{P}_{INV} = \mathbf{A}_L (\mathbf{A}_L^t \mathbf{A}_L)^{-1} \quad (16)$$

fundamental spectra $[\mathbf{C}_n^*]$; $n=1\sim N$ are uniquely generated from a given set of \mathbf{C}_{LABn} , while a metameric black \mathbf{B}_n is an arbitrary random vector with zero stimulus to human vision. However, the input devices make non-zero response to \mathbf{B}_n causing a colorimetric error. Then \mathbf{C}_n including \mathbf{B}_n should be used for testing. Although \mathbf{B}_n can't be uniquely

determined, we generated the following three different metameric blacks; $\mathbf{B1}$ from a flat gray color, $\mathbf{B2}$, and $\mathbf{B3}$ from sine SPDs with selected frequency f (cycles/ 10^3 nm) and phase ϕ .

[1] metameric black $\mathbf{B1}$ for 30% gray $\mathbf{C1}=[0.3, 0.3, \dots, 0.3]^t$

[2] metameric black $\mathbf{B2}$ for $\mathbf{C2}=[C_i]^t$; $C_i = \text{sine SPD}(\lambda_i, 3, 1.4\pi)$

[3] metameric black $\mathbf{B3}$ for $\mathbf{C3}=[C_i]^t$; $C_i = \text{sine SPD}(\lambda_i, 5, 1.4\pi)$

Where,

$$C_i = \text{sine SPD}(\lambda_i, f, \phi) = 0.25[1 + \sin\{2\pi f(\lambda_i - 400)/1000 + \phi\}] \quad (17)$$

Thus, three sets of uniform LAB chips are generated by adding the metameric black $\mathbf{B}_n = \mathbf{B1}$ or $\mathbf{B2}$ or $\mathbf{B3}$ to $[\mathbf{C}_n^*]$.

Fig.4 shows the spectra of three different metameric blacks.

The color distribution of virtual test chips by the proposed method is shown in Fig.1 (c), where, for example, \mathbf{C}_{LABn} ; $n=1\sim 933$ chips are generated inside an ellipsoid in the range of $10 \leq L_n^* \leq 90$ and $-70 \leq a_n^*, b_n^* \leq 70$. Fig.2 summarizes the flow diagram of proposed testing method.

4. Results

The following three devices are tested in the experiments.

- [1] Wratten filters (#25, #58, #47B)
- [2] RGB CCD sensor
- [3] Color Scanner.

The spectral shapes are shown in Fig.3.

In general, the spectral sensitivities are different from ideal color matching functions (Luther condition). These differences can be reduced by performing a linear matrix operation (filter correction) on the tricolor signals. The sensor goodness should be measured after filter correction, because any linear combinations of color matching functions are also color matching functions. The correction matrix \mathbf{M}_c can be determined by the method of least squares as

$$\mathbf{M}_c = (\mathbf{A}^t \mathbf{R} \mathbf{F})(\mathbf{F}^t \mathbf{R} \mathbf{F})^{-1}, \quad \mathbf{R} = E[\mathbf{C}_n \mathbf{C}_n^t] \quad (18)$$

where \mathbf{R} is the correlation matrix for \mathbf{C}_n . Matrix \mathbf{R} reflects the statistical characteristics of the color chips to be matched by the linear transformation.

The projection operator \mathbf{P}_{Fc} after filter correction in Eq. (5) is calculated by

$$\mathbf{P}_{Fc} = \mathbf{R} \mathbf{F} (\mathbf{F}^t \mathbf{R} \mathbf{F})^{-1} \mathbf{F}^t \quad (19)$$

Fig.5 shows how the tested sensors extract the fundamental metamers from an example of virtual spectrum with $\mathbf{C}_{LABn} = [L_n^*, a_n^*, b_n^*]^t = [70, -30, 20]^t$ and where the spectral error happens. CCD sensor causes larger spectral error than Wratten for this sample, though it works almost better than Wratten for ISO/DIS 12641 chips. This means the error comes from metameric black spectrum and virtual chips give more severe test than the real chips. While, color scanner works almost perfect after filter correction, because the spectral shape \mathbf{F} is carefully designed as compared with that of CCD. Table 1 summarizes the spectral errors for these sensors tested by ISO/DIS 12641, sine-SPDs and \mathbf{C}_{LABn} targets. $E[\|\mathbf{e}_c\|^2]$ and $E[\|\mathbf{e}\|^2]$ denote the results with and without filter correction.

As clearly shown in Table 1, the goodness of the tested three sensors is evaluated as

Color scanner > CCD sensor > Wratten filter

All the estimated values are consistent with the results by real chips and sine SPDs. The spectral sensing errors for both sine SPDs and proposed SPDs are almost the same order, but larger than that of real ISO/DIS 12641 target.

5. Discussion and Conclusion

The design of spectral sensitivities of color image sensors is very important to guarantee the high definition image quality in total system. Here we discussed on the spectral errors in the input color sensor from a point of how it can extract the correct fundamental spectrum. The red sensitivities of Wratten and CCD sensor seem to be intuitively mismatched to color matching functions. These undesirable spectral shapes make non-zero responses to metameric black spectra and cause colorimetric sensing errors. Thus, the color sensors' error depends on the spectral shapes of input colors with same XYZ values but different metameric black spectra. However, ISO/DIS 12641 color chips, made of photographic material, have the smoothed spectral shapes without higher frequency components in their Fourier transform. This will be the reason why ISO/DIS 12641 chips bring the smaller metameric black errors than that of sine SPDs or proposed virtual SPDs. Furthermore, the color gamut of photographic chips are limited inside the small region, while the proposed virtual chips can be distributed in any desirable wider

ranges. In conclusion, the use of computer generated virtual color targets has the following advantages.

[1] Uniform distributions [2] Tunable and wider color gamut [3] Quick estimation without real chips.

However, the way to generate the metameric black spectra is not uniquely decided. Future works should be continued to find the better virtual test targets available for designing the high definition color sensors in real world.
